Abstract

This review evaluates the available evidence on the relationship between consumption of refined grains and health outcomes. A total of 135 relevant articles were identified from database searches of studies published between 2000 and 2010. The great majority found no associations between the intake of refined grain foods and cardiovascular disease, diabetes, weight gain or overall mortality. A few studies found that very high intakes might be associated with some types of cancers, but at moderate levels of consumption the risks were not significant. The totality of evidence shows that consumption of up to 50% of all grain foods as refined grain foods (without high levels of added fat, sugar or sodium) is not associated with any increased disease risk. Nonetheless, eating more wholegrain foods remains an important health recommendation, and most consumers will need to reduce their current refined grain consumption to no more than one-third to one-half of all grains in order to meet the targets for wholegrain foods.

Sponsorship: Go Grains Health & Nutrition Ltd is a membership-based organisation that links the Australian grains industry value chain from grain growers to food manufacturers, providing scientifically based information about the role of grains and legumes in health and nutrition, to develop educational resources to support health promotion and education. Go Grains Health & Nutrition Ltd commissioned a nutrition academic from the University of Wollongong to conduct an independent literature review. The author, acts as a paid scientific advisor to Go Grains, but confirms the sponsor had no role in writing this review.
INTRODUCTION

Cereal grains are staple foods providing an important source of essential micro- and macro-nutrients, and form part of the dietary patterns recommended throughout the world. Dietary guidelines generally distinguish plain cereal products (part of the core food groups that should form the foundation of a healthy diet) from cereal-based products with significant amounts of added fat and sugar, such as cakes, pizza or pastries.

Walker, Burkitt, Cleave and Trowell pioneered the concept that highly-refined foods contribute to Western diseases and this spurred several decades of research interest in the dietary fibre content of the diet. More recently attention has turned to wholegrain foods, recognising that not only their fibre content, but also other properties related to their provision of resistant starch, vitamins, minerals, phytoestrogens and antioxidants, may protect against chronic disease. Over the last two decades, research into the benefits of wholegrain cereal foods has strengthened. In particular this has been demonstrated in relation to reduced risks of coronary heart disease, becoming overweight, diabetes and certain cancers.

The 2010 US Dietary Guidelines include the advice to consume at least half of all grains as wholegrains (which in a 2000 calorie diet equates to three or more ounce-equivalents of wholegrain products per day). They also advise people to “limit the consumption of foods that contain refined grains, especially grain foods that contain added fats, added sugars, and sodium”. The 2007 revision of the Canada’s Food Guide also included the recommendation to make at least half of your grain products whole grain each day, and there has been a recent recommendation for 4 servings of whole grain per day in Denmark.

However, despite these guidelines, the actual consumption of wholegrain foods is very low. There are substantial barriers to increasing consumption of wholegrain foods, including traditional preferences for refined products, limited availability in supermarkets and unfamiliarity with cooking techniques. Cross-country studies in...
Europe have reported that consumers expect wholegrain products to be healthier, but also believe that they will be less pleasant to eat. In the UK, wholegrain consumption has been reported to have decreased since 1986 to just 14g per day in 2000-2001, and 29% of adults report consuming no wholegrain foods. In the US it is estimated that less than 15% of total grain consumption is wholegrain and only 6-8% of adults meet the target of three servings per day. In Australia the last National Nutrition Survey estimated that the average adult daily intakes were 83g of wholegrain cereals and grains and 188g of refined cereals and grains – so that almost 70% of grain foods were refined.

Given these low levels of wholegrain consumption, many reviews of the relationship of dietary patterns to disease prevention have made recommendations to reduce refined grain consumption and increase consumption of wholegrains. However rarely do such recommendations give specific guidance about what level of refined grains can be safely included in a healthy diet. It is unlikely that advice to entirely exclude popular foods like white bread, rice or pasta from the diet would be acceptable to most consumers, nor that this is necessary.

The purpose of this review was to evaluate the evidence between consumption of refined grains and health outcomes and, if possible, answer the question: “What proportion of refined grains can be consumed in a healthy diet?”

**METHODS**

A search for original studies and reviews was carried out in the following databases: Scopus (which includes Medline and Science Direct) and PubMed in the period 2000-2010. The following search terms were used: *refined grain, refined cereal, refined starch, refined carbohydrate*. Studies were limited to those published in English and conducted in humans. The references in retrieved papers were also examined individually to supplement the electronic search.
For the purposes of the review, whenever possible, studies were chosen which reported results for core refined foods, not cereal-based foods with large levels of added fat, sugar or sodium. Examples of such core refined grain foods include: *Breads* (eg, white bread, bagels, crumpets, tortillas); *Breakfast cereals* (eg, low fibrecereals and those containing <25% wholegrain); *Refined cereal grains* (eg, white rice, polenta, semolina, couscous); *Pasta and noodles* based on white wheat or rice flour (ie not wholemeal varieties). Foods that were excluded were refined cereal-based foods with large levels of added fat, sugar, or sodium (eg, cakes, pastries, cookies, doughnuts, pizza) and whole-grain and high-fiber cereal foods.

In some of the studies selected for inclusion desserts or other high fat/high sugar foods had been included in the refined grain category, but the results did not suggest adverse health outcomes.

A total of 396 articles were identified from the initial search and their abstracts reviewed. Of these only 96 were directly relevant to the topic. The others were excluded because they did not report outcomes related to refined grains (255), were conducted in animals or patients with established disease conditions (39), were editorial or commentaries without original data (4), or were duplicates of other articles (2). Hand searching of bibliographies added a further 39 references to make a total of 135 articles for review.

The types of articles were: studies of dietary patterns of clusters (38); cross-sectional studies of foods and health relationships (20), case-control studies (13), prospective longitudinal studies (31), randomised controlled trials (9) and reviews and meta-analyses (24).

Articles were reviewed to rate the study quality, using the methods of the American Dietetic Association Evidence Analysis Manual. The ADA system results in three categories of rating: Positive, Neutral, or Negative. All the retrieved articles judged relevant to be included in this review were of Positive or Neutral quality.
RESULTS

1) Studies of dietary patterns
In the literature search, a total of 38 studies were identified that reported the impact of food patterns with different levels of refined grain foods. These covered a range of different health outcomes, including: total mortality; obesity and metabolic syndrome; diabetes; cardiovascular disease; cancer; pulmonary disease; depression and anxiety.

In addition one meta-analysis of prospective studies related to the prevention of type 2 diabetes has been published. This meta-analysis of 10 dietary pattern studies concluded that those most consistently associated with the prevention of type 2 diabetes were characterised by high consumption of fruit and vegetables, whole grains, fish and poultry, and by decreased consumption of red meat, processed foods, sugar sweetened beverages, and starchy foods.

However, such studies are only of limited use in attempting to define the level of refined grains that can be incorporated into a healthy diet, for several reasons:

1) A single pattern that is called a “high refined grain pattern” by the authors often contain mixtures of “core” low fat grain foods and also “non-core” refined grain foods which may high in added fat, sugar or sodium (e.g., pizza, doughnuts, cakes, and biscuits) as well as other non-cereal high carbohydrate foods (e.g., soft drinks, potatoes, confectionery)

2) Refined grain foods may appear in several patterns at different levels of consumption

3) The term “Western diet” has been used in a number of publications examining disease risk, but the grain foods contained in this pattern varies considerably between studies

4) In some pattern studies, core refined grain foods are split between different dietary patterns

5) It is rarely possible to relate results of dietary pattern studies to actual intakes of specific foods.
For all the reasons given above, it is difficult to use the results from dietary pattern studies to draw conclusions about the how particular levels of refined grain foods might impact health outcomes. Better data is available from studies that have looked specifically at the consumption of individual foods.

2) Cross-sectional studies
Eighteen cross-sectional studies were identified that reported the association of consumption of refined grain foods with a range of health outcomes, although most only report risk of obesity or metabolic syndrome. Of these, five found no relationship \(^{71, 72-75}\), three reported some protective effects \(^{76-78}\), and ten reported a positive association between refined grain food and adverse health status \(^{79-88}\). Although cross-sectional studies do not have a high level of explanatory power in nutrition studies \(^{89}\), the results are briefly summarised below for the purpose of providing a complete picture of the evidence.

*Studies showing lack of relationship or protection*
Most of the studies that reported no relationship were those examining measures of obesity, body fat distribution, or markers of the metabolic syndrome. In four cross-sectional surveys of 24600 subjects in Finland, bread consumption (which is predominantly wholegrain - 60% rye and 40% wheat bread - in that country \(^{90}\)) was either not associated (in men) or inversely associated (in women, OR=0.94) with obesity (BMI>30)\(^{77}\). In Brazil, a survey of 48470 households found no significant relationship between the prevalence of obesity and any of the following foods: rice, bread, biscuits, pasta, white flour \(^{71}\). In contrast, consumption of sugar, soft drinks and ready-to-eat meals were significantly correlated. In a representative cross-sectional sample of 39640 Portuguese adults, the odds ratios of obesity for bread were 0.91 for men and 0.85 for women (neither statistically significant) \(^{76}\). For “other starchy food” (pasta, rice and potatoes), consumption was significantly protective for women (OR=0.65) but not for men (OR=0.92)
In the US, an ancillary analysis from a 3-year trial of vitamin K supplementation with 434 adults found that refined grain consumption was not associated with BMI, % body fat or trunk fat mass. Two reports from the Framingham Offspring Cohort have studied refined grain foods. The first study of 2941 subjects found no association with body mass index (BMI), waist-to-hip ratio (WHR), waist circumference (WC), blood pressure (BP), lipids, insulin or glucose, with refined grain servings up to a median intake of 38 per week in the highest quintile (≈ 5.5 servings/d). The second study with 2834 subjects examined insulin resistance and presence of the metabolic syndrome. The metabolic syndrome was not associated with refined grain intake. Similar findings were reported amongst 1516 participants in the Baltimore Longitudinal Study of Aging. There was no relationship with BMI, weight, WC, overweight (BMI>25), cholesterol, fasting glucose, or hypertension up to a median refined grain intake of 103g/d in the highest quintile.

Lastly, a study of prostate cancer rates in 71 countries found that apparent consumption of up to 1800 calories per day from cereal grains (rice, wheat and maize) correlated strongly with decreasing prostate cancer mortality.

Studies showing increased risk

In a subsample of healthy adult participants from the Framingham Heart Study, visceral adipose tissue (VAT) was positively associated at high intakes of refined grains, although the lowest VAT was recorded with 2 servings of refined grains and 3 servings of wholegrains per day. In contrast, waist circumference and subcutaneous adipose tissue were not significantly associated with refined grain intakes up to 4 servings per day in the highest quintile.

In a small convenience sample of 159 US college students, participants were grouped by BMI category and the intakes of whole and total cereal grains compared by analysis of variance. Total grain intakes were similar in normal and obese subjects (around 5.5 servings/d) but a significantly higher percentage were wholegrain in the normal weight group (14.8%) compared to obese participants (5.9%). However, even for the normal weight subjects, 85% of total grain foods were from refined grains.
In a cross-sectional sample of 827 adults in Tehran mean refined grain consumption was 201g/d, ranging up to 362g/d in the highest quartile, and the associations with health states have been reported in two publications\textsuperscript{81,82}. Obesity and diabetes were not associated with refined grain intake, but the highest quartile of consumption was significantly associated hypercholesterolemia (OR=1.23), hypertriglyceridemia (OR=1.14), hypertension (OR=1.69), hypertriglyceridemic waist (OR=2.1) and metabolic syndrome (OR=2.25). At the level of consumption in the second quartile (156g/d) these associations did not appear to be statistically significant. In a second Iranian survey of 2000 adolescents, there was a reported significant linear association between BMI and the frequency of consumption of rice, bread, pasta, fast foods and fat/salty snacks\textsuperscript{83}. The mean frequency of intake (times/week) of subjects who were not overweight (with a BMI <85\textsuperscript{th} percentile) were: bread (10.8), rice (6.8), pasta (2.1).

Two studies from India also report adverse associations of high intakes of refined grain (primarily white rice) with higher waist circumference (WC), blood pressure (BP), fasting blood glucose, serum triglyceride, low HDL cholesterol, insulin resistance and diabetes prevalence\textsuperscript{84,85}. However the intakes of cooked rice were very high, ranging from 218g/d in the lowest to 584g/d in the highest quartiles, which are two to three times higher than typical intakes in Western countries.

From North America, three studies provide some evidence of increased risk with refined grains. Data from 1088 participants in the Insulin Resistance Atherosclerosis Study was used to examine cross-sectional relationships between grains and three inflammatory proteins in plasma (PAI-1, CRP and fibrinogen)\textsuperscript{86}. Refined grain intake was positively related to PAI-1, indicating it could have pro-inflammatory effects, but was not related to the other two markers.

A study in Boston of 535 adults with a mean age of 72 years used a 3-day diet record to estimate grain intake and measured a range of metabolic risk factors\textsuperscript{87}. No significant association were found between intakes of refined grains and all cause or
CVD mortality. Those in the highest quartile of intake (6.1 servings per day) had significantly higher risk of metabolic syndrome (OR=2.16), but in the second quartile (median of 2.9 servings/d) there was no significant difference.

Many of these cross-sectional studies have limitations based on lack of detail about the foods included within the refined grain category, and all suffer from the general problem that such studies cannot explore the temporal relation between consumption and health endpoints to infer causation. Furthermore five of the ten studies showing some adverse associations were conducted in non-Western countries with significantly different food patterns from those in the US, UK or Australia. Overall, however, from these studies, there is no strong evidence that consumption of a moderate intake of up to three servings of refined grains per day is incompatible with a healthy diet.

3) Case-control studies

There were 13 case-control studies: 10 for various cancers and 3 for ischemic heart disease, summarised in Table 1.

In 2001, a review of case-control studies of diet and cancer risk in Italy suggested that refined grain intake was associated with increased risk of stomach, colorectal, breast, upper-digestive and thyroid cancers. Since then ten more case-control studies on cancer risk have been published, seven of which found a significant increase in risk at the highest level of refined grain consumption (for renal, upper-digestive, stomach and colorectal cancer), while two examining pancreatic cancer and one on colorectal adenomas found no relationship. Of those showing increased risk, two for colorectal cancer only found this at the highest intake – not at the third quartile and the third such study did not present results for levels below the highest quartile.

Two case-control studies of risk of cardiovascular disease have reported no association with refined grain intake while one Chinese study found an
increased risk of stroke at very high levels of cooked white rice - above 1100g per week. Overall, therefore, there is a lack or consistency in the case-control data about cancer that makes it difficult to draw clear conclusions. Some of the increased risks are only present at the very highest levels of intake, which is still consistent with safe intakes at lower levels. The small number of case-control studies on ischemic heart disease risk do not suggest any significant risk with moderate refined grain consumption, but better data is available from the larger number of prospective cohort studies reported in the next section.

4) Prospective cohort studies
Longitudinal cohort studies provide some of the strongest evidence on which recommendations for dietary intakes can be based. Table 2 summarises 31 recent studies that have examined refined grain intake and health outcomes.

Only five studies reported an association with adverse health outcomes. Two of these studies used definitions of refined grains that included high fat cereal-based foods such as pizza, cakes and biscuits; one analysed refined grain food plus potatoes, one did not define the foods included but focused on energy density (a quality associated with greater consumption of non-core refined grains), one found an effect for women but not men, and one stated a conclusion without providing any detailed results, so caution is required when interpreting these results.

The great majority (26/31) of the longitudinal studies found no association or a protective effect for cardiovascular disease, type 2 diabetes or metabolic syndrome, various cancers, weight gain, all-cause mortality, inflammatory disease, and periodontitis. The data on CVD is consistent with a recent meta-analysis of cohort studies which concluded that while wholegrains were consistently protective, there was no evidence of differences in risk of CVD events when comparing groups with high vs low refined grain intake.
5) Intervention studies

While results from case-control and cohort studies can be powerful, they can only indicate associations between diets and health outcomes, rather than provide evidence of causal relationships. High consumption of refined grain foods may be markers of less healthy lifestyle practices, such as lower physical activity, smoking, and higher fat and alcohol intakes. Good quality epidemiological studies attempt to control for such factors, but they cannot reliably predict outcomes when diet patterns are changed, and randomised controlled trials are therefore even better evidence of the effect of diet components. Regrettably there are very few diet intervention trials that are available to consider, and most are limited by small numbers of participants and short follow-up periods.

A total of nine relevant studies were identified. None was designed to examine the effects of different levels of refined grain intakes specifically; most were attempting to increase wholegrain intake or lower the GI of diets, using refined grain foods as controls. Table 3 summarises these studies, which largely focused on cardiovascular and metabolic risk outcomes. Only one reported the energy provided by the refined grain intake in the study; others reported frequency of intake.

Six of the nine studies reported no significant differences between diets high in refined versus wholegrain cereal intakes. One of these papers reported plasma antioxidant status (with the ORAC method) rather than more direct measures of health status. Since the antioxidant content of wholegrains has been postulated to be one of the mechanisms by which they reduce cardiovascular disease risk, the lack of difference found when comparing refined and wholegrain diets suggests that having some grains in the refined form will not adversely affect antioxidant status. One reported superior reductions in % abdominal fat reduction with a wholegrain hypocaloric diet intervention, but there were still improvements to a lesser extent with the refined grain diet as well. Similarly, in the large New Zealand study, waist circumference was reduced to a greater extent on the wholegrain diet, but also reduced with the control diet, with increased consumption...
of refined cereals. One small study suggested a breakfast including refined grain rice/corn cereal improves satiety in overweight women, but there were no measures of food intake, and the results contradict similar studies in the past. Lastly, the Iranian study, reported better weight outcomes with the wholegrain interventions compared to refined grains, but the wholegrain diets were combined with energy reduction, while the controls with a higher content of refined grains did not attempt to alter the energy content, so it is not possible to draw any clear conclusions.

Most of these few studies do not show any difference in health outcomes when refined grains are compared to wholegrains, which can be interpreted to support a conclusion that some core refined grain foods can be included in a diet without increased risk to health.

6) Reviews and Meta-analyses

Almost all of the identified reviews were primarily concerned with the health benefits of wholegrains or low GI diets, and none specifically reviewed the levels of refined grain consumption in relation to health outcomes.

Three reviews looked at the question of weight control. Van Dam and Seidell’s non-systematic review examined the general issue of carbohydrate intake and obesity and concluded that wholegrain cereals, vegetables, legumes and fruits seem the most appropriate source of dietary carbohydrate, but did not report any studies of refined grain intake. Gaesser’s systematic review looked at carbohydrate quality in relation to body mass index and concluded that while wholegrain intake was generally inversely associated with BMI, refined grain intake is not consistently linked to higher BMI. This is consistent with the conclusion of the systematic review of Williams et al, which reported no clear association of refined grains with BMI. They noted there were three cohort studies reporting that higher intakes of refined grains were associated with increases in waist circumference and BMI in women, but the weight changes, although statistically significant, were relatively
minor in absolute terms: <0.7kg over a 12 year period. Liu has suggested that large and long-term intervention trials are needed to assess the effects of wholegrain versus refined grains on weight loss and maintenance.

Four systematic reviews have examined risk of cardiovascular disease. In 2002 Truswell concluded there was no clear association between total cereal consumption and CHD. Anderson’s review and meta-analysis showed a significant risk reduction of 29% with the highest wholegrain intake, but cereal fibre was not associated, suggesting other components of the grain may be protective. That review did not make any conclusions about refined grain specifically. Flight and Clifton’s review in 2006 also concluded that wholegrains are clearly protective in relation to CHD but that data on refined grains is not consistent. The most recent meta-analysis published in 2008 did specifically report on refined grains and concluded there was no evidence of increased or decreased risk for cardiovascular events when comparing high versus low refined grain intake; OR(CI)=1.07(0.94-1.22).

Five recent reviews have summarised studies relating refined grain intake to risk of cancer. La Vecchia’s non-systematic summary of a series of case-control studies in Italy concluded that refined grain consumption was associated with a moderate increase in risk of five cancers (stomach, colorectal, breast, upper-digestive and thyroid cancers), but not at 15 other sites. Later systematic and non-systematic reviews of pharyngeal and other oral cancer risks have also suggested inconsistent results in relation to refined grains. In 2007, the World Cancer Research Fund’s systematic review of Food, Physical Activity and the Prevention of Cancer concluded that there was too little evidence about the relationship of cereals and grains to draw any conclusions about cancer risk.

Finally, in relation to prevention of diabetes, most reviews have recommended changes to lower glycemic index diets, rather than specifically focusing on refined grains. One editorial hypothesised that the very high intakes of refined
white rice found in China (6 servings per day) and India (8.5 servings per day) may explain the high levels of diabetes in those populations.\(^{147}\)

**DISCUSSION**

This review has focused on health outcome studies and did not consider the nutritional adequacy of diets with different levels of refined grain intake. However, diet modeling for the latest revision of the Australian dietary guidelines showed that diets including one-third of grains foods as refined was compatible with the nutritional adequacy of the total diet\(^ {28}\) and the US Dietary Guidelines also showed nutritional adequacy was achievable with half of grain foods as refined\(^ {19}\). The great majority (45/61) of the case-control, cohort, intervention studies and reviews summarised here found no clear association between refined grain intake and adverse health outcomes. However in 16 studies there was an increase in health risk at the highest level of consumption. In some of these cases the highest quantile of intake was often extremely high compared to typical Western intakes (eg, rice intakes in India and China) and does not provide useful guidance as to the risk at lower intakes. More importantly in 7/16 studies showing increased risk, the definition of refined grain foods included high-fat or sugar-added products like pizza or cakes, so it is not possible to draw conclusions from those results about the effect of core refined grains alone.

Table 4 summarises nine studies which reported increased health risk at the highest intakes of refined grains but also provided sufficient information to allow calculation of the lower levels of intake at which there was no increase in risk. These data can provide guidance as to what level could be recommended in a healthy diet.

It should be noted that these studies relate to only a few specific health outcomes; none look at total morbidity or mortality. Most of the studies present results as amounts or numbers of servings per day. The reported frequencies range from 2.4-5.9 servings per day, with a mean of 4 refined grain servings per day. However it is difficult to relate these to total grain intakes. Only two of the studies specified the
highest proportion of all grains that could be refined without increased risk, and these ranged from 57-67% \(^{93,110}\).

Table 5 summarises the evidence base, using the format of guidelines from the Australian National Health and Medical Research Council for the evaluation of evidence \(^{89}\). It should be noted that the dietary pattern studies were not considered in establishing this summary, since few of these studies reported the amount of refined grains in the different dietary patterns. Cross-sectional studies are still listed in the table, but they provide only low-level supportive evidence rather than being the primary justification for the final evidence statement.

**CONCLUSION**

Most of the dietary guidance to reduce refined grains is based primarily on the evidence supporting increased wholegrain consumption, rather than particular concerns about risks of refined grains per se. The protective effects of wholegrains are well established, and in order to promote increased consumption there has to be a decrease in the refined grain food alternatives. However this is difficult to achieve. Even in the best large intervention trials, with high levels of education and support - eg, the 18-month trial in New Zealand \(^{137}\) – compliance with increased wholegrain targets was relatively poor.

The totality of evidence shows that consumption of up to 50% of all grain foods as refined grain foods (without significant added fat, sugar or sodium) is not associated with any increased disease risk. Nonetheless, eating more wholegrain foods remains an important health recommendation, and most consumers will need to reduce their current refined grain consumption to no more than one-third to one-half of all grains in order to meet the targets for wholegrain foods. It needs to be noted that this conclusion about refined grains only applies to core refined grain cereal foods. In all communications with the public the importance of limiting cereal-based foods that are high in added fat, sugar and sodium still needs to be emphasised.

<tbody>
<tr>
<td>Liu et al (2003) ^8 ^</td>
<td>74,091 females in Nurses Health Study USA Cohort followed every two years since 1976, with 126-item FFQ and self-reported weight. Multiple regression analysis of data from 1984-1996</td>
<td>Sweet rolls, cakes, desserts, white bread, pasta, English muffins, muffins or biscuits, refined-grain breakfast cereals, white rice, pancakes or waffle, pizza Q1: 0.4 servings/1000kcal/d Q3: 1.05 servings/1000kcal/d Q5: 2.27 servings/1000kcal/d</td>
<td>Weight, BMI, OR of developing BMI≥30</td>
<td>At baseline, mean weight of women in highest quintile of refined grain intake weighed 1.2kg more than those in the lowest quintile (BMI 25.2±5 vs 24.6±4; p&lt;0.001) Over 12 years, higher refined grain consumption was related to greater weight gain 1.65±0.03kg vs 0.99±0.03kg (p&lt;0.001) and risk of becoming obese: OR=1.18 (1.08-1.28); p&lt;0.0001).</td>
</tr>
<tr>
<td>Koh-Banerjee et al (2004) ^9 ^</td>
<td>27,082 men aged 40-75 years at baseline in the Health Professionals Follow-Up Study. USA Longitudinal prospective study 1986-1994. Multiple linear regression examined changes in grain intake and weight using self-reported weights and 131-item FFQ administered in 1986, 1990, 1990.</td>
<td>Grain foods with &lt;25% whole-grain content by weight, such as cooked and cold breakfast cereals, dark bread made with wheat flour rather than wholewheat flour, white bread, English muffins, bagels or rolls, pancakes or waffles, white rice, pasta, cookies, doughnuts, brownies, sweet rolls, coffee cake, and pizza</td>
<td>Weight</td>
<td>For every 40g/d increment in whole-grain intake, weight gain was reduced by 0.49kg. Wholegrain foods contributed only 3.3g/d of out of daily total of 27.2g grain foods/day It is stated that refined grain cereals were positively related to long-term weight gain (p for trend &lt; 0.001), but no results data are provided.</td>

<tr>
<td>Halkjaer (2004) 102</td>
<td>1200 women and 1236 men aged 30-60y in the MONICA 1 study, recruited 1982-3 and followed up in 1987 and 1993. Denmark. Diet assessed with 26-item FFQ and weight measured. Multiple linear regression examined associations of weight change and intakes of 10 food groups.</td>
<td>n/a</td>
<td>BMI and waist circumference</td>
<td>For men, a high intake of refined bread, rice and pasta tended to be associated with a subsequent decrease in WC, but the effects were not statistically significant. For women a high intake of rice and pasta also tended to be associated with decreased WC, but refined bread was significantly associated with increased WC ($\beta=0.29$; $p&lt;0.05$).</td>
</tr>
<tr>
<td>Halkjaer et al (2006) 100</td>
<td>22,570 women and 20,126 men aged 50-64y in the Danish Diet, Cancer and Health Study, Denmark. 5 year follow-up of longitudinal prospective study commenced 1993-97. Linear regression analysis of baseline diet assessed by 192-item FFQ, and self-reported weight and WC.</td>
<td>Refined grain cereals (white bread, white flour, rice, rice flour, potato flour, corn flour, and pasta) and potatoes  Median intakes at baseline: Men: 1.26MJ/d Women: 0.90MJ/d</td>
<td>Waist circumference</td>
<td>CHO from refined grains and potatoes was significantly associated with WC increase in women: 0.48 (0.18-1.78) cm; $p=0.002$ but not men: 0.06 (-0.12-0.25)cm; $p=0.49$.</td>
</tr>
<tr>
<td>Savage et al (2008) 101</td>
<td>192 white women in a longitudinal study of parental influences on girls’ growth and development, USA. Data collected on 4 occasions across 6 year. Mixed model analysis, using dietary data from 24-h recall telephone interviews</td>
<td>Not defined</td>
<td>Energy density (ED) tertiles: T1: &lt;1.5kcal/g T2: 1.5-1.85kcal/g T3: &gt;1.85 kcal/g</td>
<td>ED was positively associated with weight gain over 6 years (6.4kg vs 2.5kg; $p&lt;0.001$). Women consuming high energy density diets consumed more servings of refined grains (5.0 servings/d) compared to those in the T1 groups (3.9 servings/d); $p&lt;0.05$.</td>

<td>Positive quality</td>
<td>1379 healthy children aged 2-5y in North Dakota, USA. The cohort has been followed every two years since 1976 using a validated 84-item FFQ and self-reported weight. Multiple regression analysis estimated association of diet and weight change.</td>
<td>Bread and grains food group included rice, spaghetti and sauce, pizza, macaroni and cheese, bread, hot and cold cereals, pancakes, English muffins, biscuits and cornbread.</td>
<td>Annual weight change</td>
<td>There was a 0.16 (0.20-0.12)kg lower weight increase per year with each additional daily serving of breads and grains (p&lt;0.01)</td>
</tr>
</tbody>
</table>
| Bazzano et al (2005)   | Neutral quality | 17,881 men aged 40-84 recruited in 1982 in the Physicians Health Study, USA. Diet assessed annually with 61-item FFQ for 13 years of follow up. Cox’s proportional hazards model used to calculate relative risks. | Breakfast cereals divided into wholegrain (>25% whole grain or bran content) or refined grain cereals.  
Q1: rarely  
Q2: 1 serving/week  
Q3: 2-6 servings/week  
Q4: ≥1 serving/ day | Body weight gain  
BMI ≥ 25  
RR of weight gain >10kg | Over 8 years, compared to men with the lowest intake of refined grain cereals, men with the highest intake of refined grain breakfast cereals had:  
Less weight gain (0.94± 0.16 vs 1.46±0.05kg; p=0.005)  
Risk of BMI ≥ 25, RR=0.81(0.64-1.03); p=0.03  
After 13 years of follow up, men with the highest intake of refined grain breakfast cereals had the lowest risk of more than 10kg weight gain: RR=0.77 (0.56-1.06); p=0.05. |
